

CORONA

Disease model(s)

Rainer Heintzmann

S: susceptible

I: infected

R: removed

Quarantined

Age (everywhere)

S
susceptible

$ii(t) I + iq Q + ih H$
+ external $i0$

I
infected

- You are cured, if you survived the time series.
- If in hospital, you cured if you survive till the last time bin
- In hospital there is a chance to need intensive care
- Everyone still in intensive care has a chance to die (per day)

not measured, but immune

C
cured

$q(t)$

simulated dead

External Parameters:

- Influx of infected ppl. (travel data influencing the infection rate)
- Contact awareness (decreasing the infection rate)
 - Model: sigmoidal curve (midpoint, width, offset)

Steerable (political) Parameters (should be available as time traces):

- Quarantine: influencing q , modelled as delta peaks and time span
 - Model: unknown effectiveness of measure (e.g. Δq)
- Travel restrictions (changing the infection rate from external)
 - Model: unknown effectiveness of measure (e.g. Δr_0)
- Performing more testing (changing the detection and therefore quarantine rate d)

Axes (each state splits into sub-states according to these axes):

- Age groups (is there a standard? How to deal with different standards? Base data (local age distribution)
 - Model: Sigmoidal rates (midpoint, width, offset)
- Virus strain migration (see <http://nextstrain.org>)
- District, Region, Country
 - Model: Individual t_0 event with unknown t_0 and I_0 (how to make this differentiable?)
- Gender
 - Model: separate rates (M/F)
- Disease Progression (works like a queue with progression-dependent transition rates)
